Lab 1: Weight Discrimination

Introduction

Classical methods of psychophysics involve the measurement of two types of sensory thresholds: the absolute threshold, RL (*Reiz Limen*), the weakest stimulus that is *just* detectable, and the difference threshold, DL (*Differenz Limen*), the smallest stimulus increment that is *just* detectable (also called the Just-Noticeable Difference, the JND). Gustav Theodor Fechner (1801–1887), in *Elemente der Psychophysik* (Fechner, 1860) introduced three psychophysical methods for measuring absolute and difference (JND) thresholds: the method of adjustment; the method of limits; the method of constant stimuli. The purpose of this exercise is to give you experience with the measurement and computation of the JND for lifted weights using the method of constant stimuli.

Experiment

You will determine difference thresholds for weight discrimination using the method of constant stimuli for two different standard weights: 100 and 200 grams. One of the foundations of psychophysics is Weber's Law. It states that the difference limen is a constant proportion of the standard:

$$\frac{\Delta I}{I} = k \qquad \text{Weber's Law}$$

In this experiment you will test the hypothesis that Weber's constant is the same for two different standard weights, thus validating Weber's Law.

Procedure

In the method of constant stimuli, a standard stimulus is compared a number of times with other fixed stimuli of slightly different magnitude. When the difference between the standard and the comparison stimulus is large, the subject nearly always can correctly choose the heavier of the two weights. When the difference is small, errors are often made. The difference threshold is the transition point between differences large enough to be easily detected and those too small to be detected.

Each of you will serve as subject and as experimenter. You will use the method of constant stimuli to measure your ability to discriminate small differences in weight using two standard weights: 100 grams and 200 grams. Since there are two different standard weight conditions there are two possible testing orders. You should test yourself in the order assigned to you.

Lab 1: Weight Discrimination

Testing Orders

Order No	1st	2nd
1	100	200
2	200	100

The experimenter (E) presents a pair of weights (the standard and one of the test weights listed on the data sheet) to the observer (O). He / she arranges a support for the preferred arm of the subject or observer (O) so that his / her hand will extend over one weight. By flexion of the wrist O should be able to pick up the weight that E has placed in the appropriate position. O should lift the standard weight first (100 or 200 grams) and then the test weight and judge whether the test weight was heavier or lighter than the standard. The person recording the data needs to know the actual weight of the test weight. If the test weight was judged heavier, a "+" should be recorded on the data sheet. If the test weight was judged lighter than the standard, an "-" should be recorded. The test weights should be scrambled on the table and presented in a "random" order.

O should now be blindfolded, or turn his / her face away so that he / she gets no visual cue as to which weight is presented. E then gives O the necessary instructions:

1. "When I say, 'Now,' lift the standard weight which is directly below your hand, using a wrist motion. Notice its weight, return it to the table, and lift your hand again. When I repeat, 'Now,' do the same with the second weight."

2. "Report whether or not the test (second) weight seems **heavier** than the standard weight. **Do not give 'equal' judgments**. Guess if you are not certain."

3. E should now present the weights in pairs, placing first the standard weight and then a comparison weight directly below O's hand. E should try to develop a regular rhythm. Stimuli should be presented for 1–2 sec. duration, separated by an equal period of time. The intervals between pairs should be longer. Allow the subject to rest from time to time. At least 10 presentations of each test stimulus should be made. The order of the test weights should be randomized.

Data Tabulation and Analysis

1. Transfer the frequency of "heavier" and "lighter" judgments for each test weight from your data sheet to the summary sheet at the end of this handout. Compute the total of heavier and lighter judgments and then compute the

probability of making a heavier judgment.

2. Start up KaleidaGraph graphing application on one of the Macintosh computers. The empty data window will have three columns. Double-click on the column heading ("A") to open the dialog window and change the headings "A," "B," and "C" to "Weight," "100 prob," and "200 prob". Now type the weights 75, 80, …, 125, and 175, 180, …, 225 in the first column. Enter the probability of saying "heavier" in the appropriate columns. Select Gallery from the menu and make a graph of your data.

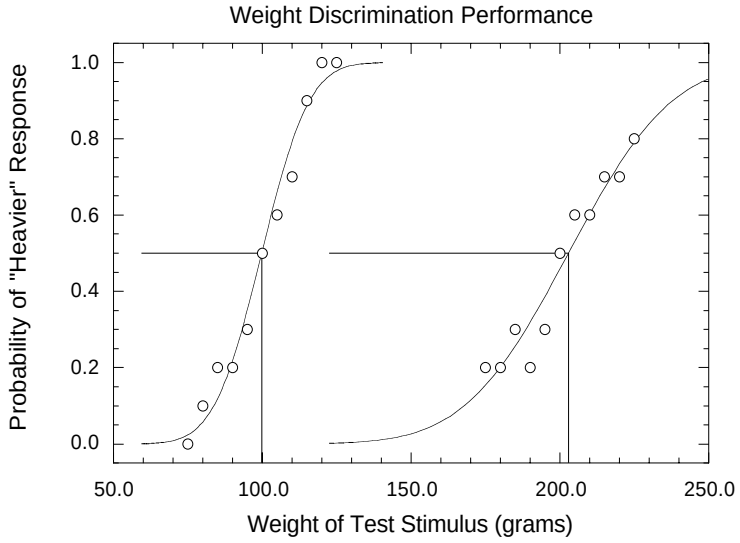
3. Next you will use the computer program **PsychoFit** to fit a smooth, S-shaped psychometric function (Gaussian Integral Function) to your data. Open the template data file "PsychoFitDataTemplate.dat" by double-clicking on it and replace the last two data columns with your own data (frequency of heavier and lighter judgments). Edit the two title lines to include your own name. When you are finished, choose SaveAs… from the File menu and save the file as a Text File with your own name (e.g., LewHarveyData.dat).

4. Double-click on the PsychoFit application and type the name of your data file when the program asks you. You my give a carriage return in place of an output file name. The program will then ask for four pieces of information: type *n* in response to the first three and 0 (zero) to the fourth. The program will use a maximum-likelihood curve-fitting technique to find the best-fitting Gaussian integral psychometric function for your data.

5. The results of the analysis will appear in a window. Print this window to save the results. Of the fitted parameters, alpha and beta are directly relevant. Alpha is the point of subjective equality (PSE) and beta is the reciprocal of the just noticeable difference (JND).

6. Using KaleidaGraph, plot both your data and the best-fitting psychometric function. Your horizontal axis, the abscissa, should cover the range from 50 to 250 grams. The vertical axis, the ordinate, plots the probability of judging the test stimulus "heavier" than the standard. It should cover the range from -0.05 to 1.05. PsychoFit creates an output file containing all the data you need. The file is called GaussianPF.out. Import the data into KaleidaGraph using the Import command from the File menu. To make the plot select Line in the submenu Linear under the Gallery main menu item. A dialog box will appear asking you to select variables to plot. Choose log stimulus (not stimulus) for the x-axis, and probability, probability (Gaussian), and markers for the y-axis. Your graph should look something like this:

Lab 1: Weight Discrimination



7. **The JND**: There are two ways to estimate the JND. One way is to compute the reciprocal of the steepness of the best-fitting psychometric function. The steepness is given by the parameter beta. So the steeper the function, the smaller the JND. Computed this way, one JND is equivalent to one standard deviation of the Gaussian distribution underlying the psychometric function.

   The second, equivalent method, is to use the difference, in grams, between the standard and the weight corresponding to the 0.84 point on the ordinate of the graph. This difference i the positive ΔI (JND of increment). The difference between the standard and the weight corresponding to the 0.16 point is the negative ΔI (JND of decrement). Estimate these two JND values from your graph (there is an easy way to do it using KaleidaGraph). Then average the two JNDs to get the best estimate of the JND.

   Compute the Weber fraction for the 100 and the 200 gram standard by dividing the appropriate JND by the corresponding standard weight. Is the Weber fraction constant?

8. **The PSE**: The point of subjective equality (PSE), is the stimulus which is psychologically equal to the standard. This point is given by the parameter alpha from the curve-fitting and is the stimulus weight that gives a probability of 0.5. You can also estimate the PSE by taking the average of the weight at 0.16 and 0.84. In a situation where no constant errors operated, the PSE should equal the standard. The discrepancy between the physical midpoint of the series (the standard) and the psychological midpoint of the series (PSE) is defined as the constant error (CE) where CE = PSE - Standard Weight. A negative CE means that the first stimulus of a pair seems less than it “actually” is. Where this can be attributed to the time elapsing between the

first and second stimuli of a pair this is called the time error.

9. **Hypothesis Testing**: We will assemble your individual data into a single StatView data file that will be available next week. Test the hypothesis, using the StatView computer program, that the value of the Weber fraction is the same for 100 grams as for 200 grams. The most appropriate analysis is a repeated measures analysis of variance.

Lab Report

Your lab report should be brief and contain four sections: cover sheet, methods, results, and discussion. These sections should conform to the American Psychological Association (APA) style (American Psychological Association, 1994) as described in Chapter 13 of the Martin textbook (Martin, 2000). The results section should have the graph described above and a table giving the PSE and JND for the 100 and 200 gram conditions. Do your results support Weber's Law?

The report is due at the beginning of the third lab meeting (18 or 20 September 2001). Late labs will receive a grade of zero. All lab reports must be prepared with a word processor. This lab report is worth 30 points.
